

# CS 6301.008.18S Lecture—April 10, 2018

Main topics are `#metric_embeddings`, the `#JL_lemma`, and `#Bourgain's_theorem`.

## Prelude

- Please sign up for presentations.
- The projects do not need to be completely done by presentation time, but I do want to hear about the work you've done by then.

## Metric Spaces

- Often we'll want some way to compare different objects to tell how similar they are.
- We've been dealing with these kinds of comparisons all semester with points. Usually we care about their Euclidean distance.
- We also saw an example with more complicated objects. For example, we looked at the Fréchet distance between two curves.
- These kinds of distances can be generalized into something we call a metric space.
- A *metric space*  $(X, d)$  consists of a (possibly infinite) set  $X$  and a *distance function*  $d : X \times X \rightarrow \mathbb{R}_{\geq 0}$  such that
  - $d(x, x) = 0$  for all  $x$  in  $X$  (an element is distance 0 from itself)
  - $d(x, y) > 0$  for all distinct  $x, y$  in  $X$  (different elements have non-zero distance)
  - $d(x, y) = d(y, x)$  for  $x, y$  in  $X$  (distances are symmetric)
  - $d(x, y) + d(y, z) \geq d(x, z)$  for all  $x, y, z$  in  $X$  (distances follow the triangle inequality)
- Points in  $\mathbb{R}^d$  form a metric space under Euclidean distance. Curves in  $\mathbb{R}^d$  form a metric space under the Hausdorff and Fréchet distances.
- We often like to talk about general metric spaces  $(X, d)$ , because the triangle inequality is enough to show some interesting results.
- For example, you can define the  $k$ -center problem for any metric space  $(X, d)$  where  $X$  is finite with  $n$  elements: just find a collection  $C$  in  $X$  of size  $k$  that minimizes the maximum distance from any element of  $X$  to an element of  $C$ .
- This problem is NP-hard, because it's a generalization of the version we saw where  $X$  was a subset of points in the plane.
- But, assuming you know the  $\binom{n}{2}$  distances, that algorithm by Gonzalez we saw works perfectly fine and gives you a 2-approximation.
- The PTAS requires more structure, though, so you really do need something like points in  $\mathbb{R}^d$ .
- Similarly, you can approximately solve the traveling salesperson problem of visiting every element of a metric while trying to minimize the total distance between consecutive pairs

of elements from your sequence of visits. As long as you know the distances, you can get a  $3/2$ -approximation.

## Metric Embeddings

- But maybe you don't want to store, or even compute, all the  $\binom{n}{2}$  distances. If you're working with very high dimensional objects or points, these computations can be very expensive.
- One solution is to map the elements of your metric into elements of another one that's easier to work with. But then you usually distort the distances.
- Given two metric spaces  $(X, d_X)$  and  $(Y, d_Y)$ , a function  $f : X \rightarrow Y$  is called a  $D$ -embedding if there exists a scaling factor  $r > 0$  such that for all  $x, x'$  in  $X$ 
  - $r d_X(x, x') \leq d_Y(f(x), f(x')) \leq D r d_X(x, x')$ .
- In other words, some distances may shrink and others may increase, but they all change the same up to a  $D$  factor.
- A 1-embedding scales all distances by exactly the same factor. It's essentially the same metric, so we call it an *isometric embedding*.
- Generally, you hope to find embeddings into much simpler metrics while keeping  $D$  as small as possible.
- But that isn't always possible depending on what your requirements are.
- For example, consider the *graphic metric*  $(V, d)$  for a graph  $G = (V, E)$ . Here,  $d(u, v)$  is the number of edges in the shortest path from  $u$  to  $v$ .
- Suppose we want to simplify an arbitrary graphic metric on a graph  $G$  by embedding it into some spanning tree of  $G$ .
- Well, if  $G$  is a cycle on  $n$  vertices, this is a problem. You'll have to remove an edge between some pair of vertices  $u$  and  $v$ . But now the distance between  $u$  and  $v$  has increased by a factor of  $(n-1)!$  On the other hand, many other distances are exactly preserved. You get an  $(n-1)$ -embedding.
- There are cases where you get much better results, though.

## The Johnson-Lindenstrauss Lemma

- Let's say we have  $n$  points in  $\mathbb{R}^d$  where  $d$  is a large number.
- Working with such high dimensional points is difficult, so we'd like to map them to a lower dimensional Euclidean space, but we don't want to distort the distances much.
- Fortunately, there's a fairly simple randomized algorithm for finding a good mapping.
- "Lemma" (Johnson-Lindenstrauss): Let  $X$  be a set of  $n$  points in  $\mathbb{R}^d$ , and fix  $0 < \delta < 1$ . There exists a  $(1 + \delta)$ -embedding of  $X$  into  $\mathbb{R}^k$  (using Euclidean distances) with  $k = O((\log n) / \delta^2)$ .

- It's going to be helpful to work with a set  $V$  of "vectors" instead of "points".
- We'll specifically show if you fix a  $0 < \epsilon < 1$ , and let  $k \geq 4 * (\epsilon^2 / 2 - \epsilon^3 / 3)^{-1} * \ln n$ , then there is an embedding where  $(1 - \epsilon) \|u - v\|^2 \leq \|f(u) - f(v)\|^2 \leq (1 + \epsilon) \|u - v\|^2$  for any pair  $u, v$  in  $V$  where  $f : \mathbb{R}^d \rightarrow \mathbb{R}^k$ .
- Choose  $\epsilon$  correctly in relation to  $\delta$  to get the JL-lemma.
- The transformation is fairly simple. We'll going to choose a random  $k$ -dimensional subspace  $S$  of  $\mathbb{R}^d$  and find the projection of every vector in  $V$  to this subspace. Then we'll just scale things outward again so the expected squared length of a vector remains is equal to its squared length before the projection.
- We'll show that an arbitrary vector has its squared length off from the expected value by a factor more than  $(1 \pm \epsilon)$  with probability at most  $O(1 / n^2)$ . There's only  $(n \text{ choose } 2)$  differences vectors for members of  $V$ , so there is a less than 1 probability than *any* of the squared lengths we care about will change. Meaning, some projection is fine.
- To talk about length changes, its enough to discuss the distribution for the squared length of an arbitrary *unit vector* to a random subspace.
- But that's difficult to reason about, so instead let's fix the subspace and look at the squared length of a random unit vector projected to the subspace. It's the same distribution. For simplicity, we'll use the space spanned by the first  $k$  coordinates, so the projection is just those first  $k$  coordinates.
- Alright, so how do you choose a random vector? Let  $X_1, \dots, X_d$  be  $d$  independent Gaussian  $N(0, 1)$  random variables, and let  $Y = 1 / \|X\| (X_1, \dots, X_d)$ . I'm going to claim without proof that  $Y$  is a point chosen uniformly at random from the  $d$ -dimensional sphere  $S^{d-1}$ .
- Let  $Z$  in  $\mathbb{R}^k$  be the projection of  $Y$  onto its first  $k$  coordinates (so the projection onto our fixed subspace).
- Let  $L = \|Z\|^2$ , the squared length we care about.
- Let  $\mu = E[L]$ . We have  $\mu$ 
  - $= E[X_1^2 + \dots + X_k^2] / E[X_1^2 + \dots + X_d^2]$
  - $= (E[X_1^2] + \dots + E[X_k^2]) / (E[X_1^2] + \dots + E[X_d^2])$
  - $= k / d$ , because each  $X_i$  comes from the same distribution.
- So, now we need to argue that the distribution of  $L$  is tightly concentrated around  $k / d$ . This requires some subtle probability arguments, but they ultimately lead to this lemma:
- Lemma: Let  $k < d$ , then
  - If  $\beta < 1$ ,  $\Pr[L \leq \beta k / d] \leq \exp((k / 2)(1 - \beta + \ln \beta))$ ,
  - or if  $\beta > 1$ ,  $\Pr[L \geq \beta k / d] \leq \exp((k / 2)(1 - \beta + \ln \beta))$
  - where  $\exp(.) = e^{(.)}$ .
- So as  $\beta$  gets away from 1, the expression  $1 - \beta + \ln \beta$  gets more and more negative, and quickly. Choosing larger values of  $k$  just causes that negativity to grow even faster.

- And since its all in an exponent, that means the probability drops very fast as  $L$  gets away from the mean of  $k / d$ .
- OK, why do we choose  $k \geq 4 * (\text{eps}^2 / 2 - \text{eps}^3 / 3)^{-1} * \ln n$ ?
- To define our map  $f : \mathbb{R}^d \rightarrow \mathbb{R}^k$ , let  $S$  be the random  $k$ -dimensional subspace we're going to project into, and let  $v_{i'}$  be the projection of each  $v_i$  in  $V$  to  $S$ .
- Now, consider any pair  $v_i, v_j$ , let  $L' = \|v_{i'} - v_{j'}\|^2$ , and let  $\mu' = (k / d)\|v_i - v_j\|^2$  be the expected value of  $L'$ .
- By the lemma,  $\Pr[L \leq (1 - \text{eps})\mu']$ 
  - $\leq \exp((k / 2)(1 - (1 - \text{eps}) + \ln(1 - \text{eps})))$
  - $\leq \exp((k / 2)(\text{eps} - (\text{eps} + \text{eps}^2 / 2)))$ 
    - (here, I used the first couple terms of the Taylor expansion for  $\ln$  implying  $\ln(1 - x) \leq -x - x^2 / 2$  for all  $0 \leq x < 1$ )
  - $= \exp(-k \text{eps}^2 / 4)$
  - $\leq \exp(2 \ln n) = 1 / n^2$
- Similarly,  $\Pr[L \geq (1 + \text{eps})\mu']$ 
  - $\leq \exp((k / 2)(1 - (1 + \text{eps}) + \ln(1 + \text{eps})))$
  - $\leq \exp((k / 2)(-\text{eps} + (\text{eps} - \text{eps}^2 / 2 + \text{eps}^3 / 3)))$ 
    - ( $\ln(1 + x) \leq x - x^2 / 2 + x^3 / 3$  for all  $x \geq 0$ )
  - $= \exp(-(k(\text{eps}^2 / 2 - \text{eps}^3 / 3)) / 2)$
  - $\leq \exp(-2 \ln n) = 1 / n^2$
- We'll use the map  $f(v_i) = (\sqrt{d / k}) v_{i'}$ .
- We just argued that for any pair of vectors  $v_i, v_j$  in  $V$ , the probability that  $\|f(v_i) - f(v_j)\|^2 / \|v_i - v_j\|^2$  does not lie in the range  $[1 - \text{eps}, 1 + \text{eps}]$  is at most  $2 / n^2$ .
- There are  $\binom{n}{2}$  pairs, so the probability that some pair suffers large distortion is at most  $\binom{n}{2} * 2 / n^2 = 1 - 1/n$ .
- By sticking a larger constant next to the  $\ln$ , you can make the probability of failure as low as  $1 / n^c$  for any constant  $c$  you desire, meaning we even have a randomized Monte Carlo algorithm for computing a good projection.
- If you have time to test projection quality, then the algorithm is Las Vegas instead.

## Bourgain's Theorem

- I'd like to finish by discussing something a bit weaker, but more general.
- Let  $(X, d)$  be any metric space over  $n$  elements. Bourgain's theorem says there is an  $O(\log n)$ -embedding of  $X$  into  $O(\log^2 n)$ -dimensional Euclidean space.
- I won't go into the proof at all, but I'll give the surprisingly simple construction.
- For every  $1 \leq i \leq c \log n$  (for sufficiently large  $c$ ), for every  $1 \leq j \leq \text{ceil}(\log n)$ , independently construct a set  $A_{\{i, j\}}$  where each element in  $X$  is selected with probability  $2^{-j}$ .
- Now, define  $d(x, A_{\{i, j\}}) = \min_{y \in A_{\{i, j\}}} d(x, y)$  to be the distance from  $x$  to the subset

$A_{\{i j\}}$ .

- Finally, let  $f(x) = \langle d(x, A_{\{i j\}}) \mid 1 \leq i \leq c \log n, 1 \leq j \leq \text{ceil}(\log n) \rangle$  which is a vector in  $O(\log^2 n)$ -dimensional space.
- Again, I won't prove it, but  $f$  is an  $O(\log n)$ -embedding with non-zero probability if  $c$  is sufficiently large.
